Trajectory Optimization with Dynamic Obstacles Avoidance

Philippe Weingertner and Minnie Ho
pweinger@stanford.edu minnieho@stanford.edu

Abstract

We study the problem of Trajectory Optimization for Autonomous Driving where we derive a motion plan on a pre-defined path. The challenge is to avoid ten vehicles crossing our path, optimizing efficiency and comfort, while making decisions in real-time. As part of a Model Predictive Control (MPC) setup, we propose a Collision Avoidance model based on an Elastic Model handling disjunctive constraints. We investigate different optimization algorithms: Interior Point methods and an adaptation of a the Simplex algorithm to a problem initially defined over a quadratic cost function. We provide reference implementations of the MPC setup, the Collision Avoidance Model, and a fully custom solver. Finally we benchmark and demonstrate the efficiency of our collision avoidance model, both in terms of accuracy and real-time performance, on a series of 100 randomly generated tests.

1 Introduction

This project investigates trajectory optimization [7] in the presence of obstacles [20, 3, 10, 21]. One such application for this class of problems is that of autonomous driving, where we have an ego vehicle and dynamic obstacles (vehicles, pedestrians) which may intersect our desired trajectory and which we wish to avoid using motion planning and control.

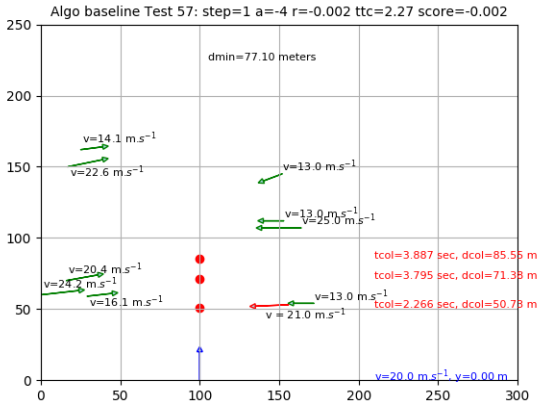

Figure 1: Collision Avoidance Scenario

We see from Figure 1 that our ego vehicle, represented by the blue vector starting at coordinates (200,0) and moving upwards along a one-dimensional path, may collide with other dynamic obstacles,

shown in green (no collision) or red (collision). The predicted collision points along the path are depicted in red. We note that an interval around the collision point can be defined as "avoidable" regions with a safety margin.

Trajectory optimization minimizes a cost function which takes into account start and terminal states, as well as cost along the trajectory path. The design space is subject to constraints on the states and the control input at sampled time points.

2 Related Work

A detailed survey of Motion Planning techniques for Autonomous Driving is provided in [17, 10]. In order to enable real-time applicability, the problem is typically decomposed in a two-stage process. First a path is planned and then a Motion Plan is derived over this pre-defined path (or over a set of pre-defined paths). This strategy has been in use since the DARPA challenge [20, 4, 19, 8]. Path planning typically relies on search algorithms (e.g., A*, D*, or RRT*) [9, 16], while the derivation of a Motion Plan over a path typically relies on either pre-computed velocity profiles or by solving an online optimal control problem.

While MPC is well-established for pure trajectory tracking assuming there exists a collision-free trajectory we want to follow [13], it can also be used to derive a collision-free trajectory. In the first case, a more complex and non-linear vehicle dynamics model is used, while in the second case, a linear approximation of the dynamics is used to quickly derive a collision-free trajectory. This collision-free trajectory is then further refined in terms of comfort and vehicle dynamics feasibility.

We focus on the Motion Planning problem where a path is pre-defined, and we want to derive a collision-free trajectory considering a linear approximation of the vehicle dynamics. There are several publications investigating the use of MPC to derive a collision-free velocity profile [14, 3, 18]. These assume that a higher level planner has already decided whether an ego vehicle proceeds or yields to any other vehicle crossing its path. While this may be a reasonable strategy when dealing with a single or two dynamic obstacles, we would like to scale to multiple crossing objects, deciding individually and optimally for each object whether to proceed or yield as part of the optimization problem.

3 Problem Formulation

We define a MPC problem over 20 time steps of 250 ms each, using a Quadratic Cost function with $x \in \mathbb{R}^{2x20}, u \in \mathbb{R}^{20}$ and 160 constraints. Here, every column of x represents a two-element vector, defining the ego vehicle's position and velocity, such that $x_k = [s, \dot{s}]'_k$ and the acceleration command is represented as $u_k = \ddot{s}_k$.

We have 120 linear inequality constraints, which bound the position, velocity, and acceleration; up to 10 nonlinear inequality constraints, where the nonlinear constraints represent the avoidance of an interval around a potential collision point; and 43 linear equality constraints, which represent the linear Dynamics Model and the initial condition.

Thus, we have the following optimization problem:

$$\min_{u_0,\dots,u_{T-1}} (x_T - x_{\text{ref}})\, Q_T\, (x_T - x_{\text{ref}}) + \sum_{k=0}^{T-1} (x_k - x_{\text{ref}})\, Q\, (x_k - x_{\text{ref}}) + u_k\, R\, u_k$$

$$\text{subject to } \begin{cases} x_{k,\text{min}} \leq x_k \leq x_{k,\text{max}} \\ u_{k,\text{min}} \leq u_k \leq u_{k,\text{max}} \\ x_{k+1} = A_d x_k + B_d u_k \\ x_0 = x_{\text{init}} \\ \forall\, (t_{\text{col}}, s_{\text{col}})_{i \in [1,10]} \qquad x_{t_{\text{col}}^{(i)}}[1] < s_{\text{col}}^{(i)} - \Delta_{\text{safety}} \text{ or } x_{t_{\text{col}}^{(i)}}[1] > s_{\text{col}}^{(i)} + \Delta_{\text{safety}} \end{cases}$$

We want to avoid up to 10 vehicles crossing our path. The spatio-temporal collision points $(t_{\text{col}}, s_{\text{col}})$ are defined with an associated uncertainty area $t_{\text{col}} \pm 250\ ms,\ s_{\text{col}} \pm \Delta_{\text{safety}}$ for the position of the ego vehicle with respect to a predicted collision point.

We use a linear dynamics model with constant acceleration in between every two time steps:

$$\begin{bmatrix} s \\ \dot{s} \end{bmatrix}_{k+1} = A_d \begin{bmatrix} s \\ \dot{s} \end{bmatrix}_k + B_d \left[\ddot{s}\right]_k \text{ with } A_d = \begin{bmatrix} 1 & \Delta t \\ 0 & 1 \end{bmatrix}, B_d = \begin{bmatrix} \frac{\Delta t^2}{2} \\ \Delta t \end{bmatrix}$$

4 Methods

4.1 Collision Avoidance Model

We reformulate the collision avoidance model and later on demonstrate the improvements it provides in a set of benchmarks. An implementation of this model is available in mpc_mip.jl.

4.1.1 Disjunctive Constraints

In general the collision avoidance constraint is defined as $\left\|\text{pos}_{\text{ego}} - \text{pos}_{\text{obj}}\right\|_2 \geq \text{d}_{\text{safety}}$

When considering the evolution of an ego vehicle along a path denoted by $s\left(t\right)$ and a crossing-point for some other vehicle, at $\left(t_{\text{cross}}, s_{\text{cross}}\right)$, the collision avoidance constraint is reformulated as: $\left|s\left(t_{\text{cross}}\right) - s_{\text{cross}}\right| \geq \text{d}_{\text{safety}}$ which is equivalent to a disjunctive constraint:

$$s\left(t_{\text{cross}}\right) \leq s_{\text{cross}} - d_{\text{safety}} \quad \vee \quad s\left(t_{\text{cross}}\right) \geq s_{\text{cross}} + d_{\text{safety}}$$

In practice, the fundamental question we should answer is whether we should proceed or yield the way w.r.t. this other vehicle. To handle this disjunctive constraint, we introduce a binary slack variable such that the OR constraint is replaced by an AND constraint as follows:

$$s\left(t_{\text{cross}}\right) \leq s_{\text{cross}} - d_{\text{safety}} + My \quad \wedge \quad s_{\text{cross}} + d_{\text{safety}} \leq s\left(t_{\text{cross}}\right) + M\left(1 - y\right)$$

$$\text{with } y \in \{0, 1\} \text{ and } M \in \mathbb{R}^+ \text{ for large enough } M \text{ so that the constraint is true when } y = 1.$$

This way, even if we have defined two constraints via the AND function above, which is required to apply optimization algorithms like Interior Point Methods or Simplex, only one or the other constraint will be active. However, by using a binary slack variable, we have to use a Mixed Integer Programming solver.

This problem reformulation corresponds to the Big-M reformulation of disjunctive constraints.

4.1.2 Elastic Model

We would like to have a convex formulation of the problem such that we can find as quickly as possible a guaranteed global minimum. The problem is that when defining a problem with such a collision avoidance constraint, we may achieve infeasibility.

$$\begin{aligned} &\min_x \quad \text{Quadratic}\left(x\right) \\ &\text{s.t. } a^T x \leq b \text{ (safety distance constraint)} \end{aligned}$$

In other words, in practice there may be no dynamically feasible motion plan to maintain a pre-defined safety distance. But we want to reveal by how much the constraint needs to be relaxed in order to become feasible. We are looking for a Motion Plan that is dynamically feasible and which violates our desired safety distance as little as possible. In order to reveal this value, we introduce another slack variable, per the collision avoidance constraint, such that the problem becomes:

$$\begin{aligned} &\min_x \quad \text{Quadratic}\left(x\right) + y \\ &\text{s.t. } a^T x \leq b + \text{y (safety distance constraint)} \\ &\text{elastic slack variable: } y \in \mathbb{R} \end{aligned}$$

If we do not use such an elastic slack variable, a convex solver would return an infeasibility verdict and Interior Point Methods would fail.

4.2 Optimization Algorithms

We use the following generic optimization formulation and notations:

$$\begin{array}{ll} \min\limits_{\mathbf{x}\in\mathbb{R}^n} & f(\mathbf{x}) \in \mathbb{R} \\ \text{subject to} & \mathbf{g}(\mathbf{x}) \leq \mathbf{0} \in \mathbb{R}^k \\ & \mathbf{h}(\mathbf{x}) = \mathbf{0} \in \mathbb{R}^m \end{array}$$

4.2.1 Penalty Methods

We first consider Penalty and Augmented Lagrangian methods [11] which transform the constrained problem into an unconstrained one via the use of the following penalty methods:

$$p_{\text{quadratic}}(x) = \sum_i \max(g_i(x), 0)^2 + \sum_j h_j(x) \quad p_{\text{Lagrange}}(x) = \frac{1}{2}\rho \sum_i h_i(x)^2 - \sum_i \lambda_i h_i(x)$$

The issue with these methods is that even if they may end up approaching a minimum, it may be from an infeasible region. This is why Interior Point Methods are usually preferred.

4.2.2 Interior Point Method with Inequality and Equality Constraints

We build upon the work that was done for AA222 Project 2. An Interior Point Method based on a Quasi-Newton method, BFGS, with backtracking Line search was implemented. But here we deal with equality constraints, of the form $Ax = b$ (corresponding mainly to our Vehicle Dynamics Model), in addition to inequality constraints. We modify the way we compute the search direction. At every step, we do a second order approximation of our minimization function. We express the Lagrangian $\mathcal{L}(x, \lambda)$ and solve for $\nabla_x \mathcal{L} = 0$. The solution of the resulting system of equations provides the new search direction: $d = \Delta x_{\text{newton\_step}}$, everything else being unchanged.

$$\min_{\text{subject to}} \begin{cases} \hat{f}(x+v) = f(x) + \nabla f(x)^T v + \frac{1}{2} v^T \nabla^2 f(x)\, v & \text{Second order Taylor approximation} \\ A(x+v) = b \end{cases}$$

Via optimality conditions on $\mathcal{L}(x, \lambda)$ we get: $\begin{bmatrix} \Delta x_{\text{newton\_step}} \\ \lambda \end{bmatrix} = \begin{bmatrix} \nabla^2 f(x) & A^T \\ A & 0 \end{bmatrix}^{-1} \begin{bmatrix} -\nabla f(x) \\ -(Ax - b) \end{bmatrix}$

The details of the derivation can be found in chapter 10 of [2] and our implementation in optimize.jl.

4.2.3 Simplex Algorithm

Because our optimization problem is essentially a quadratic optimization problem over a convex set, we use the Frank-Wolfe method [5], which takes advantage of the Simplex algorithm for a very fast implementation.

We rewrite our original problem:

$$\begin{array}{ll} \min\limits_{\mathbf{x}} & f(\mathbf{x}) \\ \text{s.t.} & \mathbf{x} \in \mathcal{D} \end{array}$$

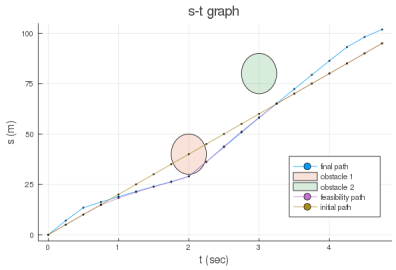
as a first-order direction-finding problem

$$\begin{array}{ll} \min\limits_{\mathbf{s}} & \mathbf{s}^T \nabla f(\mathbf{x}_k) \\ \text{s.t.} & \mathbf{s}, \mathbf{x}_k \in \mathcal{D} \end{array}$$

The problem has been converted to a linear optimization problem with respect to the variable $\mathbf{s}$, which in turn can be solved with the Simplex algorithm and updated at each time step k as follows: $\mathbf{x}_{k+1} = \mathbf{x}_k + \gamma(\mathbf{s}_k - \mathbf{x}_k)$.. We note that if the region $\mathcal{D}$ is convex and $0 \leq \gamma \leq 1$, the updated point $\mathbf{x}_{k+1}$ is feasible by definition, and this algorithm provably converges to the global minimum.

4.3 Optimization under Uncertainty

We handle uncertainty as per the set-based minimax approach described in chapter 17 of [11]. We are dealing with imperfect observations of the surrounding vehicles and with even more uncertain driving models. As a consequence, the predicted crossing point $(t_{\text{cross}}, s_{\text{cross}})$ is uncertain. This uncertainty is represented by a random variable z and the crossing vehicle can be at any location within an uncertainty area represented as a circle in the (s, t) domain; the shadow area in the ST graph (longitudinal position S along the path vs Time).



We try to avoid the whole uncertainty area, complying to the minimax approach $\min_{x \in \mathcal{X}} \max_{z \in \mathcal{Z}} f(x, z)$. If we can not avoid the full uncertainty area, we will remain as far as possible from its center, via the Elastic Collision Avoidance Model described previously. This Elastic Model strictly enforces dynamics constraints, but relaxes the safety distance as little as possible.

5 Experiments

The gihub repo is AA222-project.

5.1 Solvers Benchmarks

We benchmark different solvers including our own implementation in optimize.jl. We check:

- Constraints compliance: we have defined a set of vehicle dynamics constraints and collision avoidance constraints.
- Objective value: the lower this value, the more optimal we are in terms of efficiency (maintaining a desired speed) and comfort (minimizing jerk)
- Runtime: as we are dealing with planning steps of 250 ms, we need to have a runtime below 250 ms for real time applicability as a bare minimum. But in reality we may have to react in less than 40 ms in case of emergency.

We first check our own implementation: Interior Point method vs Penalty method. As expected the Interior Point methods outperforms the penalty methods by ensuring feasibility.

With the Interior Point method, we get:

```
OPTIMIZE.jl INTERIOR POINT METHOD
max   equality constraint violation:(1.256239e-11, 4) out of 40
max inequality constraint violation:(-0.000311, 120) out of 122
Pass: optimize returns a feasible solution on 2/2 random seeds.
```

With the Penalty method we get:

```
OPTIMIZE.jl PENALTY METHOD
max   equality constraint violation:(0.06176, 17) out of 40
max inequality constraint violation:(3.2979, 120) out of 122
Fail: optimize returns a feasible solution on 0/2 random seeds.
```

We then benchmark a set of open source solvers like ECOS and SCS with a set of commercial solvers MOSEK and CPLEX and our own Interior Point implementation optimize.jl (with maxcount set to 20K). They all provide feasible solutions which are very close, and derive same values for the slack

variables. The main difference is the runtime: ECOS and MOSEK are the fastest (we also tested Gurobi, but our trial license expired before write-up. However, it performs similar to CPLEX). As MOSEK and CPLEX are the only solvers handling both Quadratic Cost functions and Mixed Integer Programming, we will use MOSEK for our final set of benchmarks instead of ECOS: to test our Collision Avoidance model in a series of 100 tests.

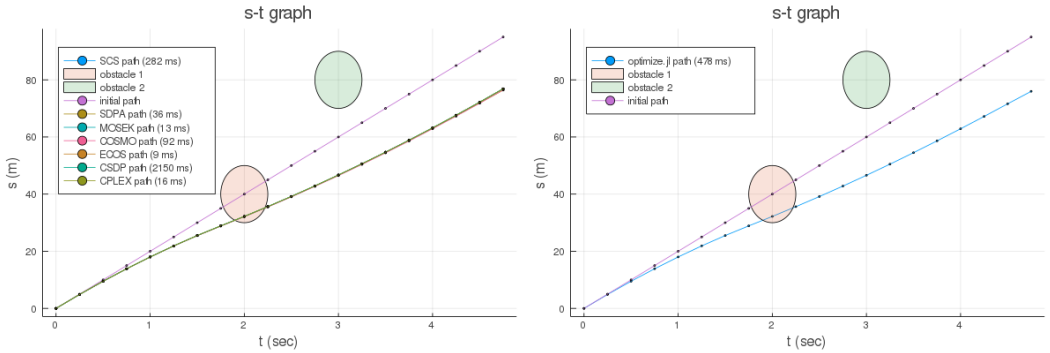


Figure 2: Solvers Runtime Benchmark

We then analyze further the runtime difference between our own implementation and MOSEK. We are using 160 BFGS iterations (40 during the feasibility search phase and 120 during interior point phase) while MOSEK just requires 20 iterations. We believe the difference is due to the fact that MOSEK implements a Primal-Dual Interior Point method instead of the raw Barrier Interior Point Method. It exhibits better than linear convergence and requires fewer iterations.

```
OPTIMIZE.jl INTERIOR POINT METHOD runtime=256 ms (maxcount set to 10K)
Iter 124 BFGS=1.62 ms: INV=0.63 ms, BT=0.38 ms, GRAD=0.40 ms
```

Also our BFGS iterations take on average 1.62 ms with:

- 0.63 ms spent doing a 100×100 matrix inversion of our approximated Hessian. This could be further improved with a direct Hessian inverse approximation.
- 0.38 ms in Backtracking line search.
- 0.40 ms in approximating Gradient via Finite Differences. By using a Complex Step approach we could probably also further improve this step.

As a conclusion, we will use MOSEK for our next set of experiments.

5.2 Anti Collision Tests Benchmarks

We use five metrics to evaluate the performance of our different approaches. (1) The main success metric is the percentage of cases where we reach a target state without collision. (2) The second metric is the agent runtime. (3) The third metric is a comfort metric: the number of hard braking decisions. (4) The fourth metric relates to efficiency: how fast we reach a target while complying to some speed limitation. (5) The last metric is a safety metric: for some of our randomly generated test cases, a collision is unavoidable. In these cases, we aim for a lower speed at collision.

Mean	Success	Runtime	HardBrakes	Steps	Collision Speed
Baseline (Constant Speed)	22%	$< 1\mu s$	0.0	40.0	20.0 m.s^{-1}
MPC	79%	19 ms	3.09	39.5	18.5 m.s^{-1}
MPC_MIP	96%	22 ms	0.19	53.8	18.7 m.s^{-1}
MPC_SIMPLEX	96%	6.9 ms	4.72	43.48	18.8 m.s^{-1}
Oracle (Dynamic Programming)	96%	22.3 sec	0.48	33.1	15.5 m.s^{-1}

Table 1: Results over 100 anti-collision tests

The Baseline is not accounting for collision constraints but is optimal w.r.t. our objective function: desired speed and minimum jerk. For the Oracle, we discretize the set of possible acceleration commands as integers in between $\left[-4\ ms^{-2}, 2\ ms^{-2}\right]$ and performs an exhaustive tree search by implementing a Dynamic Programming tree search algorithm. This enables to define lower and upper bounds for our real-time solution.

We benchmark two similar MPC implementations. The parameters are all the same except the collision avoidance model. In the first implementation we do not use the Elastic Model and the binary slack variables to deal with disjunctive constraints. Whereas with MPC_MIP we are using our proposed collision avoidance model. The safety improvement is significant: we not only outperform the reference MPC implementation but also reach our upper bound in terms of collision avoidance metric. The efficiency in terms of average speed, is somewhat degraded as we need more steps to reach the target position. But we believe we could probably improve this point further by tuning some hyperparameters of our quadratic optimization objective: as we are weighting two different objectives, comfort (minimum number of acceleration changes and hardbrakes) and efficiency (minimum number of steps) to build a single objective.

Update 10th of June, after project delivery: MPC SIMPLEX is working great now. Its is as safe as MPC MIP but 3 times faster.

6 Conclusion

We came up with a detailed analysis of a Trajectory Optimization problem. We tackle the issue of Collision Avoidance of dynamic obstacles where real-time decisions are required. We propose a Collision Avoidance model based on an Elastic Model handling disjunctive constraints. This solution is based on Mixed Integer Programming with core optimization algorithms relying on primal-dual interior point methods. We also investigate how the Simplex algorithm could be adapted to solve a problem initially defined over a quadratic cost function. Finally we demonstrate the efficiency of our proposed model, operating over a continuous state space, with a runtime of 22 ms. While being 1000 x faster than our Oracle, a Dynamic Programming implementation performing an exhaustive search over a discretized solution space, it achieves the same collision avoidance success rate.
